Model Dependence of PDG Comparison Values:

How Empirical Values Arise, Where Theory and Irrational Factors Enter, and What This Means for FFGFT Residuals

Abstract

FFGFT predictions are compared against PDG and CODATA values. This document examines how those comparison values actually arise: which raw observable underlies each, which theory (QED, Standard Model) enters the extraction, and where irrational numbers already appear in the extraction formulae themselves.

Main findings: (1) m_e and m_μ/m_e are the least model-dependent anchors, but m_μ/m_e is QED-dependent and derives from a 27-year-old muonium HFS measurement whose theory uncertainty CODATA underestimates by a factor of 5–10 (Eides 2026). (2) α carries an unresolved 5σ tension between the two best recoil measurements. (3) $v = 246$ GeV is never measured; it is the SM definition $v \equiv (\sqrt{2}\,G_F)^{-1/2}$. (4) G_F carries a theory correction $\Delta q = -0.44\,\%$ with a 4.7σ hadronic tension. (5) m_τ has two measurement methods differing by 0.18 MeV; FFGFT lies 0.4σ from the PDG average. (6) The magnitude of all theory uncertainties (10^{-7}

to 10^{-10}) does not explain the $\sim 1\,\%$ residual in $(m_\mu/m_e)^2$ — it remains physical. (7) Errors accumulate along the derivation chain; every prediction requires its full provenance path.

All 21 primary sources were verified on 5 September 2026.

1 The question

The corpus compares FFGFT predictions with PDG values and finds residuals at the sub-percent to percent level. Are PDG values theory-neutral, or do they themselves depend on the Standard Model — such that part of the residual arises on the extraction side rather than the FFGFT side?

The FFGFT foundational statement: only ratios free of irrational numbers are exact; SI absolute values are structurally approximate (Docs. 241, 085). If PDG values themselves contain irrational factors in their extraction, the same limitation applies to the comparison side.

2 How empirical values arise

No PDG or CODATA value is a raw measurement. Each passes through the same chain:

raw observable → theory formula → extracted parameter → CODATA adjustment → PDG value

The CODATA adjustment

CODATA publishes recommended values every four years, produced by a joint least-squares adjustment over roughly 300 input data linked by theory relations (QED, Rydberg formula, kinematics). The values are therefore *correlated*: a change in one input shifts all dependent values. Where theory uncertainties enter, they are partly treated as adjustment parameters (δ_{th} in the observational equations) rather than as errors — this is the Eides finding for muonium HFS **[Q]**.

Electron mass m_e

Raw observable: cyclotron frequency of a hydrogen-like ion ($^{12}C^{5+}$, $^{28}Si^{13+}$, $^{20}Ne^{9+}$) in a Penning trap, and the Larmor precession frequency of the bound electron. The ratio is a pure number.

Theory formula: bound g-factor from QED bound-state theory. From the frequency ratio and g_{bound} follows m_e/m_{ion}; with the ion mass in u follows m_e in u; conversion to MeV via u → kg → MeV.

Theory dependence: QED for g_{bound}, small and well controlled. Current: Heiße et al. (2023) at 0.1 ppb **[Q]**.

Muon-electron mass ratio m_μ/m_e

Raw observable: ground-state hyperfine splitting of muonium (a bound μ^+e^- state) — a microwave resonance at 4.463 GHz — and Zeeman splitting in a magnetic field.

How m_μ/m_e is measured. The muon is not placed on a scale. From the measured HFS frequency $\Delta\nu$ and the QED formula for the Fermi frequency

$$\nu_F = \frac{16}{3}\,\alpha^2\,c\,R_\infty\,\frac{m_e}{m_\mu}\left(\frac{m_r}{m_e}\right)^3 \tag{1}$$

(corrections: QED to $O(\alpha^3)$, recoil in m_e/m_μ, weak Z exchange, hadronic VP) m_μ/m_e follows. Two consequences:

- m_μ/m_e *is not theory-free*: the extracted value contains assumptions about α, higher-order QED loop corrections, and hadronic vacuum polarisation. Since $\nu_F \propto \alpha^2$, α enters implicitly — anchor and α are not independent.
- *CODATA overstates the real precision*: CODATA 2022 gives $\sigma_{\text{rel}}(m_\mu/m_e) = 2.2 \times 10^{-8}$. The actual uncertainty of the HFS extraction (experiment + QED theory from Eides 2026 + α tension) is $\approx 1.2 \times 10^{-7}$ — a factor of 5–6 larger. **[Q]**

Theory dependence: high. Sole precision measurement: LAMPF 1999 (Liu et al.). Eides (2026) shows that CODATA lists the measured value 4 463 302 776(51) Hz as the theoretical value; the actual theory uncertainty is 271–515 Hz **[Q]**.

Fine-structure constant α

Two routes that disagree at 5σ **[Q]**:

- **Atom recoil:** $\alpha^2 = 2R_\infty\,(h/m_{\text{atom}})\,(m_{\text{atom}}/m_e)/c$. Rb (Morel et al. 2020): $\alpha^{-1} = 137.035\,999\,206(11)$. Cs (Parker et al. 2018): $137.035\,999\,046(27)$. Difference 1.6×10^{-7}, $> 5\sigma$.
- **Electron $g-2$:** a_e at 10^{-13} (Fan et al. 2023) plus 5-loop QED (12 672 diagrams, Aoyama et al.). Gives $\alpha^{-1} = 137.035\,999\,166(15)$ — between Rb and Cs.

The CODATA value 137.035 999 177(21) is an average covering none of the measurements. FFGFT: $\alpha^{-1} = 3700/27 = 137.037\,037\ldots$ (Doc. 338, R101), deviation 7.6 ppm — 100× larger than the Rb/Cs tension.

Tau mass m_τ — two methods

Method	Experiment	Value (MeV)	Theory assumption
Threshold scan	BESIII 2014	$1776.91 \pm 0.12\,^{+0.10}_{-0.13}$	QED cross-section
Pseudomass	Belle II 2023	$1777.09 \pm 0.08 \pm 0.11$	$m_{\nu_\tau} = 0$
PDG average 2024	—	$\mathbf{1776.93 \pm 0.09}$	—

Threshold scan: $\sigma(e^+e^- \to \tau^+\tau^-)$ versus beam energy near $2m_\tau \approx 3.55$ GeV; m_τ as fit parameter of the QED threshold curve. **Pseudomass:** at 10.6 GeV, the kinematic edge of the invariant mass in $\tau \to 3\pi\nu$; assumes $m_{\nu_\tau} = 0$.

For FFGFT: $m_\tau = 1776.97$ MeV (pred) lies 0.04 MeV $= 0.4\sigma$ from the PDG average. The methods differ by 0.18 MeV. The falsification test is undecided; Belle II with > 1 ab^{-1} should reach $\sigma < 0.05$ MeV.

Fermi constant G_F and vacuum expectation value v

Raw observable for G_F: muon decay time distribution (MuLan, 10^{12} decays), $\tau_\mu = 2.196\,980\,3(22)$ μs **[Q]**.

Theory formula (Eberhart et al. 2026 **[Q]**):

$$\tau_\mu^{-1} = \frac{G_F^2\, m_\mu^5}{192\pi^3}\,(1 + \Delta q), \qquad \Delta q = (-4\,384\,678 \pm 34) \times 10^{-9} \approx -0.44\,\%. \tag{2}$$

Δq contains QED to $O(\alpha^3)$, hadronic vacuum polarisation, electron-mass effects. Purely electroweak corrections are absorbed into G_F by definition (Sirlin 1980). The hadronic component carries a 4.7σ tension (CMD-3 vs. older data).

Raw observable for v: none. $v \equiv (\sqrt{2}\,G_F)^{-1/2} = 246.22$ GeV follows from $M_W = gv/2$ and $G_F/\sqrt{2} = g^2/(8M_W^2)$. v **exists only within the Standard Model.** Its numerical value is the muon lifetime in SM clothing.

For FFGFT: Doc. 006/R104 gives $v = 248.3$ GeV (without K_{frak}) or 245.6 GeV (with $K_{\text{frak}} = 74/75$). Comparison with 246.22 GeV is a comparison of *FFGFT structure against SM definition*, not against an observable. Only τ_μ and m_μ are measured.

Gravitational constant G

Torsion balance (Li et al. 2018, 11.6 ppm) or atom interferometry (Rosi et al. 2014, 150 ppm). Theory: Newton. The only model-free value, but the least precise: CODATA $6.67430(15)\times10^{-11}$, 22 ppm **[Q]**.

Neutrino mass-squared differences

Event rates versus L/E, three-flavour fit (NuFIT 6.0 **[Q]**). Δm^2_{31} depends on whether SK atmospheric data are included: ratio 33.7 (with) vs. 33.9 (without). FFGFT $360/11 = 32.73$; measurement uncertainty 1–3 % $\approx$ FFGFT residual. Not discriminating.

Overview

Quantity	Raw observable	Theory in extraction	Convention
m_e	frequency ratio	QED (g_{bound})	—
m_μ/m_e	HFS frequency	QED, weak, hadr.	—
α (Rb/Cs)	interferometer phase	R_∞ (QED)	—
α ($g-2$)	frequency ratio	5-loop QED	—
m_τ	rates vs. E / edge	QED threshold / $m_{\nu_\tau} = 0$	beam calibration
G_F	decay times	Fermi + QED + hadr.	Sirlin absorption
v	—	—	$v \equiv (\sqrt{2}G_F)^{-1/2}$
G	angle / acceleration	Newton	—
Δm^2	rates vs. L/E	3-flavour	with/without SK-atm

No value is theory-free. For FFGFT this means: comparison with PDG values is comparison with "QED + convention", not with raw observations.

3 Irrational factors in the extraction formulae

The FFGFT foundational statement — ratios of rationals are exact, SI absolute values carry the approximation of the projection $S^1_m \to \mathbb{R}_t$ (Docs. 306, 333) — applies to the SM extraction formulae themselves:

Quantity	Formula	Irrational factor
G_F	$\tau_\mu^{-1} = G_F^2 m_\mu^5/(192\pi^3)$	π^3
v	$v = (\sqrt{2}\,G_F)^{-1/2}$	$\sqrt{2}$
α (recoil)	$\alpha^2 = 2R_\infty h/(mc)$	$R_\infty \propto \alpha^2$: implicitly circular
HFS	$\nu_F \propto \alpha^2$	α^2
Δq	expansion in α/π	π in every term

"G_F measured" means: τ_μ measured, divided by $192\pi^3$, square root taken. "ν measured" additionally means: divided by $\sqrt{2}$, square root again. The irrational factors come from the SM formulation (phase-space integral, Higgs normalisation), not from measurement. The only convention-free comparison would be at the level of $\tau_\mu = 2.196\,980\,3$ µs — which FFGFT would have to predict directly **[S]**.

4 The residual in $(m_\mu/m_e)^2$: exact computation

FFGFT bare (Doc. 338): $(m_\mu/m_e)^2 = 43200$ exactly, an integer, $= |\mathrm{GF}(9)^*|^2 \cdot 5^2 \cdot |\mathrm{GF}(27)|$. With CODATA 2022 in exact rational arithmetic:

$$(m_\mu/m_e)^2_{\text{PDG}} = 42753.12 \tag{3}$$

$$\text{residual} = 446.88 \quad (1.045\,\%) \tag{4}$$

$$\sigma_{\text{rel}}\big((m_\mu/m_e)^2\big) = 4.35 \times 10^{-8} \quad \Rightarrow \quad \text{residual} = 240\,000\,\sigma. \tag{5}$$

Possible error sources, computed:

- CODATA uncertainty: ± 0.002 — factor 2×10^5 too small.
- Eides correction to HFS theory uncertainty (515 instead of 51 Hz): ± 0.010 — residual remains $45\,000\,\sigma$.
- Choice of α in the HFS anchor (FFGFT $3700/27$ instead of CODATA): shifts $(m_\mu/m_e)^2$ by -1.3 — factor 500 too small.
- To reach 43200, m_μ would need to be 551 keV higher (measurement error 2.3 eV), or m_e 2.65 keV lower (error 0.15 meV), or the HFS 23 MHz lower (error 51 Hz).

Conclusion [B]: No measurement error explains the residual. It is physical and belongs to the theory: fractal-recursive correction (Docs. 295, 146, 338) and projection approximation (Docs. 306, 333). In the square, without square root: $43200 \cdot (1 - 77.6\,\xi) = 42753$; $K_{\text{frak}} = 1 - 100\xi$ over-corrects by $22.4\,\xi$. Which power of K_{frak} acts on the quadratic identity is not fixed in the corpus **[S]**.

Rational or irrational: where the comparison is clean

The discussion above compared three Galois identities against PDG values. Not all comparisons are equally clean:

Comparison	Galois value	Type	Residual
$(m_\mu/m_e)^2$ vs. 43200	43200 (integer)	rational	$-1.034\,\%$
m_μ/m_e vs. $\sqrt{43200}$	$120\sqrt{3}$	**irrational!**	$-0.519\,\%$
$m_e \cdot m_\mu$ vs. 54 MeV^2	54 (integer)	rational	$-0.016\,\%$

The linear comparison m_μ/m_e vs. $\sqrt{43200} = 120\sqrt{3}$ is *not a clean rational comparison*: $\sqrt{43200}$ is irrational, and the $-0.52\,\%$ residual is not an independent physical finding. It equals exactly half the quadratic residual ($-1.034\,\%/2 \approx -0.517\,\%$), because taking the square root approximately halves the deviation. Nothing new becomes visible.

Only two comparisons are algebraically clean:

- **Square:** $(m_\mu/m_e)^2 = 43200$ — both sides rational, residual $-1.034\,\%$ physical.
- **Product:** $m_e \cdot m_\mu = 54$ MeV^2 — both sides rational, residual $-0.016\,\%$ **[K]** (Doc. 338; algebraic origin: $|GF(3)^*| \cdot |GF(27)| = 2 \cdot 27 = 54$).

The product $m_e \cdot m_\mu = 54$ MeV^2 is the algebraically cleanest Galois identity with the smallest rational residual ($-0.016\,\%$). The absolute deviation is -0.0087 MeV^2 (-7386 ▯$(CODATA)/1386$ ▯$(Eides)$ CODATA, $-1386\,\sigma$ Eides) — also physical, but 65 times smaller than the quadratic residual.

Bookkeeping rule: Galois identities should be compared only in their natural algebraic form — where no irrational numbers appear. For $(m_\mu/m_e)^2 = 43200$ that is the square comparison; for $m_e \cdot m_\mu$ the product. The linear comparison m_μ/m_e vs. $\sqrt{43200}$ should be avoided because it introduces an irrational intermediate (verification script: `pruef_351_rationale_vergleiche.py`).

Is the square comparison algebraically admissible?

The identity $(m_\mu/m_e)^2 = 43200$ is admissible as a Galois comparison — both sides rational, no irrational factor. But it compares two different objects:

- **Layer-1 (purely algebraic):** The identity $(r_\mu/r_e)^2/\xi = 43200$ is exact from winding numbers ($r_\mu/r_e = 12/5$, Doc. 317) and Galois group orders ($|GF(9)^*|^2 \cdot 5^2 \cdot |GF(27)|$, Doc. 338). No measured value enters.
- **Layer-2 (empirical):** $(m_\mu/m_e)^2_{\text{PDG}} = 42753.12$ comes from the HFS measurement (LAMPF 1999), extracted via $\nu_F \propto \alpha^2$. It is a QED-dependent measured value.

Following Stefaan Vossen's precision (5 Sept. 2026): the Layer-1 object $(r_\mu/r_e)^2/\xi$ and the Layer-2 object $(m_\mu/m_e)^2_{\text{PDG}}$ are *distinguishable scientific objects*. The comparison is admissible, but the residual $\approx 78 \cdot \xi$ belongs to the Layer-1 → Layer-2 mapping, not to the algebraic identity itself. It lies far outside the SI projection range ($\approx \xi$) and is open **[S]**.

The product $m_e \cdot m_\mu = 54$ MeV^2 is the cleaner object in this sense: its residual $\approx 1.2 \cdot \xi$ lies entirely within the range of the SI projection approximation (Docs. 085, 306, 333) and is structurally explainable **[K]**. The Layer-1 → Layer-2 transition is there covered by the projection.

Two orthogonal axes: difference and sum of logarithms

The PDG masses m_e and m_μ produce two independent logarithmic projections when compared with the Galois identities:

$$\underbrace{\ln\frac{m_\mu/m_e}{\sqrt{43200}}}_{\text{difference axis}} = \varepsilon_\mu - \varepsilon_e \approx -38.99 \cdot \xi \qquad \underbrace{\ln\frac{m_e \cdot m_\mu}{54\,\text{MeV}^2}}_{\text{sum axis}} = \varepsilon_e + \varepsilon_\mu \approx -1.21 \cdot \xi$$

Difference axis: linear and square are one single finding. The linear ratio m_μ/m_e vs. $\sqrt{43200}$ (-0.519%) and the square $(m_\mu/m_e)^2$ vs. 43200 (-1.034%) lie on *exactly the same axis* $\varepsilon_\mu - \varepsilon_e$. Logarithmically it holds exactly:

$$\ln\frac{(m_\mu/m_e)^2}{43200} = 2 \cdot \ln\frac{m_\mu/m_e}{\sqrt{43200}}.$$

The square doubles the percentage but measures no new physics. It is *one* finding, two ways of writing it. The value $-38.99 \cdot \xi$ is empirical; it lies 8σ (Eides) from $39 \cdot \xi$ and is not a Galois integer **[S]**.

Sum axis: the product is orthogonal. $\varepsilon_e \approx +18.9 \cdot \xi$ and $\varepsilon_\mu \approx -20.1 \cdot \xi$ are nearly equal in magnitude and opposite in sign. In the sum they nearly cancel; what remains is $-1.21 \cdot \xi$ — the common scale deviation of both masses. This is at order ξ, consistent with the SI projection $S^1_m \to \mathbb{R}_t$ (Docs. 085, 306, 333) **[K]**. The sum ($-1.21 \cdot \xi$) does not follow from the difference ($-38.99 \cdot \xi$) — they are two independent physical pieces of information.

Combination	Logarithm	Residual	Status
$\ln\left(m_\mu/m_e\,/\sqrt{43200}\right)$	$\varepsilon_\mu - \varepsilon_e$	$-38.99\cdot\xi$	ratio residual, order 100ξ **[K]**
$\ln\left((m_\mu/m_e)^2/43200\right)$	$2(\varepsilon_\mu - \varepsilon_e)$	$-77.99\cdot\xi$	exactly $= 2\times$ above
$\ln\left(m_e\cdot m_\mu\,/\,54\,\text{MeV}^2\right)$	$\varepsilon_e + \varepsilon_\mu$	$-1.21\cdot\xi$	derivation from decompactification **[S]**

The apparently different percentages -0.016%, -0.52%, and -1.03% arise from two numbers: the generation tension ($-39\cdot\xi$) and the SI projection ($-1.2\cdot\xi$). Their large ratio is not an amplification but a cancellation in the sum (verification script: `pruef_351_generationsdifferenz.py`).

The residual of the product comparison lies at order ξ itself:

Quantity	Residual in units of ξ	Interpretation
$m_e\cdot m_\mu$ vs. 54	$-1.21\cdot\xi$	order ξ: SI projection **[K]**
$(m_\mu/m_e)^2$ vs. 43200	$-77.6\cdot\xi$	higher order: fractal-recursive **[K]**

The SI projection $S^1_m \to \mathbb{R}_t$ (Docs. 085, 306, 333) structurally produces errors of order ξ. The product residual $-0.016\,\% \approx 1.2\cdot\xi$ lies precisely in this range and is therefore structurally explainable as an SI transition approximation **[K]**. The quadratic residual $-1.034\,\% \approx 78\cdot\xi$ lies in higher order and is explained by the fractal-recursive correction (Docs. 295, 146, 338).

Result: The Galois identity $m_e\cdot m_\mu = 54$ MeV^2 is the only currently known identity whose residual lies at order ξ — the structurally expected SI projection error. The residual is therefore not unexplained; it corresponds to the approximation of the SI transition.

Constitutional description (after Stefaan Vossen, 5 Sept. 2026)

The following four-layer formulation summarises the epistemic status of the FFGFT comparisons:

Layer	Status
Layer-1	Exact within rational arithmetic: $(m_\mu/m_e)^2 = 43200$ and $m_e\cdot m_\mu = 54$ MeV^2 are integer Galois identities without approximation **[B]**.
Layer-2	One empirical dimensional anchor: $m_\mu = 105.66$ MeV (PDG). All absolute predictions follow from it **[K]**.
Residual	Empirical discrepancy with a structural explanation of approximately the correct order: $(m_\mu/m_e)^2$ deviates by $\approx 78\cdot\xi$ from the PDG value (fractal-recursive correction, Doc. 295); $m_e\cdot m_\mu$ deviates by $\approx 1.2\cdot\xi$ (SI projection approximation, Docs. 085, 306, 333) **[K]**.
Quantitative bridge	The forward derivation of the exact residual from the $S^1_m \to \mathbb{R}_t$ non-isomorphism is not in the corpus. **Open [S].**

The open [S] is not a gap in the pejorative sense but a precisely constituted limit: the theory states explicitly where its formal construction stops.

Methodological note (after Stefaan Vossen, 5 Sept. 2026)

> *"Constitution does not tell the Galois identity what it is. It tells us what a particular scientific use of that identity is presently entitled to mean."*

Two distinctions to be preserved in the record:

1. 54 **as a finite-field integer** $\neq 54$ **MeV^2 as a dimensional representation.** The identity $|GF(3)^*| \cdot |GF(27)| = 2 \cdot 27 = 54$ belongs to the dimensionless Layer-1 algebra **[B]**. $m_e \cdot m_\mu = 54$ MeV^2 is a dimensional representation produced by the mapping into SI units (Layer-2). Both are distinguishable scientific objects; the unit MeV^2 belongs to the dimensional mapping, not to the dimensionless algebra alone.
2. **Numerical correspondence vs. physical attribution.** The residual $m_e \cdot m_\mu \approx 54$ MeV^2 with deviation $\approx 1.2 \cdot \xi$ is an established numerical correspondence **[K]**. The physical attribution of that residual to the SI projection $S^1_m \to \mathbb{R}_t$ (Docs. 085, 306, 333) remains bounded by the still-open quantitative bridge **[S]**. The correspondence stands; the attribution is a proposal, not a derivation.

Methodological remark: relation vs. prediction

The three percentages (-0.519%, -1.034%, -0.016%) are *not tolerance values*. Tolerance arises only when a **calculated** mass deviates from a **measured** one — which requires an independent FFGFT prediction for m_e or m_μ individually.

The Galois identities 43200 and 54 MeV^2 are **relations** between both masses, not individual predictions. As long as no independent FFGFT value for m_μ (or m_e) exists, none of the three percentages has a defined limit.

Moreover: every direct mass carries the fractal correction K_{frak} and the SI projection $S^1_m \to \mathbb{R}_t$. In the ratio, K_{frak} cancels; the SI corrections *subtract* (difference axis, $\approx -39 \cdot \xi$). In the product, K^2 remains; the SI corrections *add* (sum axis, $\approx -1.2 \cdot \xi$). The different percentages arise from this — not from measurement errors.

No independent single prediction for m_μ without an input anchor exists in the corpus. With m_e as anchor (SETZUNG) there are two routes:

- **Square route:** $m_\mu = m_e \cdot \sqrt{43200} = m_e \cdot 120\sqrt{3}$ — irrational, deviation $+0.52\%$. Not a clean Layer-1 value.
- **Product route:** $m_\mu = 54\,\text{MeV}^2/m_e$ — rational, deviation $+0.016\% \approx 1.2 \cdot \xi$. The only rational tolerance value for m_μ at anchor m_e.

But: $m_{e,\text{PDG}}$ already carries K_{frak} and the SI projection. Hence $m_\mu^{\text{pred}} = 54/m_{e,\text{PDG}} \approx m_{\mu,\text{bare}}(1-\varepsilon_e)$ and $m_{\mu,\text{PDG}} \approx m_{\mu,\text{bare}}(1+\varepsilon_\mu)$, so:

$$\frac{m_\mu^{\text{pred}}}{m_{\mu,\text{PDG}}} - 1 \approx -(\varepsilon_e + \varepsilon_\mu) \approx -1.2 \cdot \xi.$$

This is the sum axis — the same relation as the product residual. The fractal correction does not cancel but is contained in ε_e and ε_μ and adds in the product. A true Layer-1 tolerance value for m_μ without any correction does not exist, because every direct mass carries K_{frak} and the SI projection.

5 Error accumulation along the derivation chain

Each step carries a small residual (recursion $\sim 100\xi$, projection $\sim \xi$, extraction theory 10^{-7}–10^{-10}). Already at m_μ, the first step after the anchor m_e:

Route $m_e \to m_\mu$	Residual
Galois bare: $m_\mu = \sqrt{43200}\, m_e$	$+0.52\,\%$
with $\sqrt{K_{\text{frak}}}$: $m_\mu = \sqrt{43200 \cdot 74/75}\, m_e$	$-0.15\,\%$
via α: $E_0 = \sqrt{\alpha/\xi}$, $m_\mu = E_0^2/m_e$	$+1.37\,\%$

At m_τ (second step), v (third, via $\xi^{3/2}$), each derivation accumulates further. To decide where a residual sits, convergence of empirical values onto the algebraic ones would have to be established — it is not: m_μ/m_e (1999), α (5σ tension), Δm^2_{atm} (2.4σ shift in 2024), v (not measured).

Bookkeeping: For every reported prediction, state: (1) the anchor, (2) the number of derivation steps, (3) corrections applied and where, (4) the comparison value with its extraction method. “FFGFT predicts m_μ to 0.5 %” is incomplete; complete: “From m_e (PDG), in one step via the Galois identity, without K_{frak}, m_μ follows with $+0.52\,\%$ against the 1999 muonium HFS value.”

6 Consequences for the corpus

No numerical value in the corpus changes. What changes:

1. v **is neither anchor nor observable.** Docs. 006, 319, R104: “$v = 246$ GeV (measured)” → “$v = 246$ GeV (SM definition from G_F)”. Register R112.
2. m_μ/m_e **is QED-dependent.** “model-independent” → “least model-dependent available value”; $\nu_F \propto \alpha^2$. Register R113.
3. α **has no unique measured value below 1 ppb.** Cite the comparison value as CODATA average with Rb/Cs tension.
4. m_τ**:** two methods, PDG average 1776.93(9), FFGFT 0.4σ — open.
5. **New open item [S]:** τ_μ directly from FFGFT, without detour via G_F and v — the only convention-free test of the weak sector.

Sources

All sources verified on 5 September 2026 against INSPIRE, APS, Nature, arXiv, or PubMed. Numerical values computed in exact rational arithmetic against CODATA 2022.

Derivation chains: from ξ to comparison values. Dashed boxes = external comparison values; dashed arrows = Galois identities.

1 Affected derivation chains

Which FFGFT chain depends on which comparison value, and what each finding changes.

Finding	Affected documents	Numerical correction	Wording correction
v is SM definition (R112)	Docs. 006, 319, R104	none	“$v = 246$ GeV (measured)” → “(SM definition from G_F)”
G_F: Δq, $192\pi^3$, $\sqrt{2}$	Docs. 006, R104, 319	none	state $\Delta q = -0.44\,\%$; clarify with/without Δq
m_μ/m_e QED-dependent (R113)	Docs. 338, 317, 011	none	“model-independent” → “least model-dependent”
α Rb/Cs 5σ	Docs. 011, 070, 338	none	cite CODATA average with tension
m_τ two methods	Docs. 317, 006	none	cite BESIII + Belle II; PDG average 1776.93(9)
Neutrinos Δm^2	Docs. 339, 340	none	freeze NuFIT configuration
G	Doc. A145	none	—
Total		**none**	wording clarifications

The residual $(m_\mu/m_e)^2 = 43200$ vs. 42753.12 (difference 446.9) is $240\,000\,\sigma$ (CODATA) or $45\,000\,\sigma$ (real uncertainty, Eides) of the measurement uncertainty — physical (R113). No numerical value in the corpus changes.
